BACKGROUND

- Surface water from the Rio Grande is delivered for agricultural and urban use in our region by about 700 miles of canals and laterals maintained by two irrigation districts.
- An unknown quantity of the water delivered by these canals is lost through natural seepage and evaporation.
- Texas AgriLife Research and New Mexico State University scientists are working together to conduct studies to quantify canal seepage losses and opportunities for water conservation through lining canals in both irrigation districts.

OBJECTIVES

- To determine water losses from canal seepage.
- To assess potential water savings by lining canals and delivery system improvements.
- To help irrigation districts prioritize canal lining and optimize the design of lined canals.
- To conserve water and increase available water supplies.

FINDINGS AND BENEFITS

- Research results from the canals tested show seepage losses ranging from 10% to 30% of the total amount of water delivered.
- Losses vary significantly from location to location due to different soil types and hydraulic conditions. The results show higher seepage loss rates in the upper valley than in the lower valley.
- Two different methods are being used to measure seepage losses. Ponding test results show water seepage rates from 160 acre-feet to 362 acre-feet per mile along a portion of the Franklin Canal. Another method, current meter inflow-outflow measurements, show even higher seepage losses ranging from 884 acre-feet to 1,986 acre-feet per mile during the irrigation season.
- Average savings from lining 10 miles of canals could provide water for as much as 1,000 acres of crops or 8,000 households.
- Canal lining is expensive. The results from this study are assisting irrigation districts in targeting canals that will result in the highest water conservation.
- Substantial quantities of water can be saved by reducing canal seepage losses. This research is being used to increase water delivery efficiency and extend our limited water supplies.
